## **PREFACE**

The S3A Guideline was successfully implemented in 1994. However, in recent years, analytical method sensitivity has improved, allowing microsampling techniques to be widely used in toxicokinetic (TK) assessment. This Q&A document focuses on points to consider before incorporating the microsampling method in TK studies, acknowledges its benefits, and some limitations, for assessment of TKs in main study animals and its overall important contribution to the 3Rs benefits (Replacement, Reduction and Refinement) by reducing or eliminating the need for TK satellite animals.

## **1. INTRODUCTION - SCOPE**

### ***1.1 (Q1) What is the definition of microsampling?***

**A1** For the purpose of this document, microsampling is a method to collect a very small amount of blood (typically  $\leq 50 \mu\text{L}$ ) that is generally used to measure concentrations of a drug and/or its metabolites, and subsequently calculate the appropriate TK parameters. The appropriate matrices used for microsampling techniques include blood and its derived plasma or serum, which can be used in liquid or dried form for transportation, storage and subsequent analysis. Microsampling for TKs can be used in rodents and non-rodents. Microsampling in non-blood derived matrices is outside the scope of this Q&As document.

### ***1.2 (Q2) What are the benefits/advantages of microsampling?***

**A2** Minimizing the volume of blood collection can reduce pain and distress in animals and improve the animal welfare (refinement) of rodents and non-rodents. It can also eliminate the TK satellite group in which the TK assessment is conducted in main study animals or, reduce the number of required animals in a TK satellite group when used in rodent studies (reduction). The benefit is particularly notable for mice, since a significant number of these animals are generally used in satellite groups, in TK studies using conventional sample volumes. The main scientific advantage of microsampling is that the relationship between the safety data and drug exposure can be directly evaluated in the same animal.

## **2. BASIC PRINCIPLE ON APPLICATION OF MICROSAMPLING**

### ***2.1 (Q3) For what types of pharmaceuticals and for what types of safety studies can we use microsampling?***

**A3** Generally, microsampling is applicable to the majority of pharmaceuticals including biopharmaceuticals. However, for all types of analytes, consideration should be given on a case-by-case basis as to whether the sensitivity of the measurement method is appropriate with the small sample volumes available.

Microsampling can be used in any type of toxicology study, such as single-dose or repeat-dose toxicology studies, and other toxicology studies (e.g. carcinogenicity, juvenile and reproductive studies). When microsampling is applied, sampling of a representative subgroup is acceptable, as mentioned in the S3A guideline. There are published examples demonstrating no impact on key veterinary clinical pathology or pathological parameters when small volumes of blood are taken from adult animals. However, microsampling is not warranted when the drug concentration is low and the majority or all samples are Below the Limit of Quantification (BLQ) (e.g., exposure after topical or inhaled administration). However, when the bioanalytical method for microsampling has the same Lower Limit Of Quantitation (LLOQ) with that for conventional sample volume, microsampling can be used even if majority or all samples are BLQ.

### ***2.2 (Q4) What are the points to consider when applying microsampling to TK studies?***

**A4** As with other approaches to kinetic sampling, in order to adopt a microsampling technique appropriately, a bioanalytical method should be developed and qualified (or validated for Good Laboratory Practice studies, in accordance with regulatory guideline/guidance in each region) to ensure the reliability of analytical results. Analytical characteristics, such as LLOQ, accuracy, precision, influence of matrix using dilution prior to storage and the stability of the analyte(s) in the biological matrix for the entire period of sampling, storage and processing conditions, should be carefully assessed in order to establish the microsampling method. When conventional methods have been already used in some studies and microsampling is proposed for others, a comparability of the exposure measurement, in the given matrix, between microsampling and conventional methods may be necessary. This comparison is particularly important if the conditions that the TK samples are presented in are substantially different (e.g. dried sample from microsampling vs. liquid sample from conventional sampling). This comparability can be done in a separate pharmacokinetic (PK) study to measure area under the matrix level concentration-time curve (AUC) and/or  $C_{max}$ , provided that the appropriate range of concentrations is evaluated, and

the resulting parameters compared between the two methods. This PK study, if needed, should be completed prior to conducting definitive studies that will include the microsampling procedure. A separate PK study for comparison may be omitted on a case-by-case basis and with appropriate scientific justification, for example, when using similar assay conditions to test blood, plasma or serum drawn from the same sampling site.

During this comparison process, multiple blood collections at a few time points by microsampling from a few animals and their subsequent measurement of analyte concentrations can be considered in order to check the variability of sampling. Ideally, the same matrix should be used throughout the TK studies and also in clinical studies for comparison of exposure. When different matrices are used in different studies, the drug concentration relationship among matrices should be defined considering appropriate factors such as haematological parameters, plasma protein binding ratio and blood/plasma (or serum) ratio of the drug, so that systemic exposure can be evaluated appropriately from each measurement using different matrices.

**2.3 (Q5) *What types of blood collection are used for microsampling?***

**A5** Blood can be collected from the tail vein, saphenous vein, etc., using capillary tubes or any appropriate miniaturized collection devices. The collected blood, and its derived plasma or serum, can be used to measure drug concentrations in either liquid or dried form. In some cases, liquid samples can be diluted with the appropriate vehicles or blank matrices prior to storage, shipment and subsequent analysis. Dried sample methods are also available, wherein the sample is usually applied directly onto cellulose-based or other types of materials and then dried. A fixed diameter sub-punch or the whole quantity of the sample on the card/device can be extracted and analysed. Recent and on-going advancements in microsampling methods have demonstrated the ability to collect precise volumes of blood, such that the entire sample can be used for analysis without additional volumetric measurements. In addition, newly developed techniques could also be considered with adequate validation.

### 3. EFFECT ON SAFETY EVALUATION

#### 3.1 (Q6) *How to evaluate the effect of blood sampling on the toxicity data and wellbeing of the animal in main study group?*

**A6** When blood sampling is performed on the main study animals, it is important to consider the effect of blood collection on the physiological condition of the animals. The main factors to consider include; 1) the volume and the number of samples taken in a given period; 2) the properties of the test drug (e.g. its effects on red blood cells, anticoagulant effect, or haemodynamic properties); 3) the test system (e.g. species, age, body weight, total blood volume); and 4) the site of collection. As frequent and repeated blood collection may affect physiological data, such as haematological parameters, sampling protocols should be appropriately established even with microsampling. It is prudent to record the relevant animal data, such as changes in body weight, food consumption, haematological parameters (e.g. red blood cell count, haemoglobin level, haematocrit value, mean corpuscular volume, electrolytes, total proteins), and any effect on the blood collection site (e.g. tissue damage, inflammation). Evaluation of these parameters compared to matching control animals, which have had the same number and volume of samples drawn as the test drug groups, will be important to establish whether any suspected effects are related to test drug or to procedures, within the context of the specific study conditions. If previous studies show that test drug-related changes to haematological parameters could be exacerbated by frequent blood sampling, or it is suspected that the pharmacological action of the test drug may induce such effects, the use of satellite groups of animals for TK assessment would be warranted, even if microsampling techniques are used. Alternatively, sparse sampling\* can be used in conjunction with microsampling, if scientifically justified.

\*Sparse sampling in TK studies usually involves the collection of a few blood samples at specified timepoints from each animal in a treatment group. The samples are allocated at different time points for different animals, often allowing some replicates, and statistical inferences are then made about the concentration-time behaviour of the test compound. By using proper study designs, investigators can limit the number of samples and the amount of blood drawn, so as not to affect the animals' health status, yet still achieve the customary toxicokinetic objectives in a study.

#### 4. ISSUES REGARDING THE BIOANALYTICAL METHOD

##### *4.1 (Q7) What are important points to consider in bioanalytical method development and validation of treatment of liquid or dried samples?*

A7 In addition to the analytical method validation stipulated in the bioanalytical guideline/guidance in each regulatory region, the following points should be considered when analysing samples derived from microsampling:

For liquid sampling, the following issues should be considered 1) ensuring sample homogeneity, for example by pipetting; 2) small volume handling issues (e.g. potential freezing/drying effects during the storage and subsequent freeze/thaw process, as applicable); 3) potential increase in the LLOQ due to the limited sample volume; 4) impact of addition of anticoagulants to small containers/capillaries, resulting in dilution of the sample; 5) potential for increased adsorption of the analyte to the collection container (i.e. increased surface area to volume ratio); 6) keeping the appropriate preservation conditions of the sample; 7) risk of contamination and difficulty of repeated sampling using some methods.

For dried sampling techniques (e.g. spotting onto cellulosic or non-cellulosic card, polymer matrix, etc.), it is important to select the method with adequate and reproducible recovery and minimal matrix interference with detection of the drugs. If the sub-punch of the dried spot approach is used, it is important to ensure that detection of the analyte is not affected by different haematocrit values, especially for small molecule drugs. The effect of haematocrit on analyte detection can be measured by using blood with different haematocrit values and spiking with test drugs of known concentrations. It is also important to confirm the uniformity of the spots by evaluating analyte levels from multiple samples punched out from one spot or, by evaluation, for example, using radiolabels. Both of these issues can be minimized if an accurate volume of blood is collected on the device and the entire sample is subsequently analysed.

Incurred sample reanalysis (ISR) should be conducted according to each regional guidance/guideline, if described. When doing ISR, care should be taken to ensure sufficient sample volumes or numbers of replicates (e.g. spots, containers, or tips) are retained for ISR.
